Titanium dioxide nanoparticles were prepared by hydrolysis of titanium tetra-isopropoxide. Aqueous solutions with various pH and the resultant reaction morphology on the preparation of TiO$_2$ nanoparticles were investigated. The influence of pH on the reaction morphology of using a titanium tetra-isopropoxide was evaluated depending on the amounts of the catalysts such as HCl and NH$_4$OH. The morphology and phase transformation of TiO$_2$ particles prepared by the hydrolysis of titanium tetra-isopropoxide were strongly influenced by the presence of the catalysts. In the case of using NH$_4$OH, the morphology of the TiO$_2$ particles exhibited a powder form. In the case of using HCl it showed a bulk or granular form. The phase transformations of amorphous Ti(OH)$_4$ to anatase TiO$_2$ and the anatase to rutile were significantly influenced by the type and the amount of the catalysts.

Key words : TiO$_2$ nanoparticle, hydrolysis, TTIP, pH, reaction morphology.

Introduction

Nanosized TiO$_2$ has attracted increasing attention in the scientific community for its wide applications in photocatalysts, solar cells, gas sensors and optoelectronic devices [1, 2]. The applications of TiO$_2$ arise primarily from its physicochemical properties, such as crystalline structure, particle size, specific surface area, porosity and thermal stability. Controllable synthesis of nanosized TiO$_2$ particles with these properties, especially crystalline structure, represents some of the key subjects in its applications. In recent years, semiconductor photocatalysis has attracted a great deal of research attention due to its potential application to solve environmental problems [3-5]. Among the various semiconductors employed, TiO$_2$ is versatile material and good photocatalyst for the degradation of environmental contaminants due to its high photocatalytic activity, absence of toxicity, relatively low cost, and excellent chemical stability under various conditions [6-8]. The excellent photocatalytic property of TiO$_2$ is due to its wide band gap and the long lifetime of photogenerated holes and electrons. With an appropriate light source, a TiO$_2$ photocatalyst generates electron/hole pairs to initiate a series of chemical reactions that eventually mineralize the pollutants [9, 10].

TiO$_2$ usually exists in the form of anatase, rutile and brookite. In a photocatalytic study, anatase TiO$_2$ is generally considered to be more active than rutile crystalline [11]. The anatase phase is thermodynamically metastable and easily transforms into the stable rutile phase, however, when TiO$_2$ is calcined at high temperature. Moreover, anatase TiO$_2$ with a higher crystallinity means fewer defects for the recombination of photogenerated electrons and holes [12]. Rutile TiO$_2$ has been shown to be negligibly photocative for the photo-oxidation of many organic pollutants in aqueous media, but its resistance to disaggregation is higher than that of anatase TiO$_2$ [11, 12].

The increase of the lifetime of the photo-produced pairs, due to hole and electron transfer between the two coupled semiconductors, is invoked in many cases as the key factor for the improvement of the photocactivity. Nevertheless, it should be considered that photoactivity also strongly depends on bulk and surface physicochemical properties of the photocatalysts, such as the type of phases, the surface hydroxylation, the porosity, the surface area, the adsorption capacity, the distribution of the supported photocative component, and the surface acid-base properties [13-15]. The physical, chemical, and photochemical properties of TiO$_2$ nanoparticles are dependent on the manufacturing method.

To enhance the application of TiO$_2$, several processes have been developed over the last decade and can be classified as liquid process sol-gel [16-21], solvothermal [22, 23], hydrothermal [24-26], solid state processing routes (mechanical alloying/milling) [27-30], thermal hydrolysis [31, 32] and other routes such as laser evaporation [33], and ultrasonic synthesis [34]. However, TiO$_2$ particles prepared by these processes are relatively large with inhomogeneous morphologies. From the above methods, the sol-gel method is normally used for the preparation of nanosized TiO$_2$ particles. The sol-gel process has notable advantages...
such as high purity, good uniformity of the microstructure, low temperature synthesis, easily controlled reaction conditions, and hence has been widely adopted for preparing nanostructured TiO$_2$ particles.

There are several parameters for controlling the sol-gel process to prepare TiO$_2$ particles with significant properties. It has been demonstrated that the precursor’s concentration of precursor titanium alkoxide greatly affects the crystallization behavior and the characteristics of the final particle [35-37]. The size, stability, and morphology of the sol produced from alkoxide is strongly affected by the hydrolysis and pH. The pH of the prepared solution has a great influence on the final size of TiO$_2$ nanoparticles [38-42]. The reaction morphology and the effect of the pH on the formation of TiO$_2$ particles is of great interest, because nanosized particles are formed under these conditions. Therefore, a controlled pH and reaction morphology are required for the optimization of the preparation conditions of TiO$_2$.

In this study, TiO$_2$ nanoparticles were prepared by the sol-gel route using titanium tetra-isopropoxide. The reaction morphology was investigated depending on the amounts of HCl and NH$_4$OH, and the effect of the pH on the preparation of TiO$_2$ nanoparticles was studied. Subsequently, the phase transformations of amorphous Ti(OH)$_4$ to anatase TiO$_2$ and anatase to rutile was investigated in detail.

**Experimental**

Titanium tetra-isopropoxide (TTIP, Ti(OCH(CH$_3$)$_3$)$_4$) and isopropyl alcohol (IPA, C$_3$H$_8$O) were mixed in the molar ratio of 1:10 and stirred for 1 hour. Another solution was prepared from a mixture of H$_2$O and IPA with a molar ratio of 10:1. This solution was then titrated into the TTIP-IPA solution and stirred for 2 h until a uniform colloidal TiO$_2$ sol was produced. A TiO$_2$ sol is chemically very unstable in the neutral pH range and therefore it easily agglomerates when it transforms into the gel state. However, this instability can be controlled by adding an acid. Solutions with various pH were used as the hydrolysis catalyst. The desired pH value of the solution was adjusted by adding HCl and NH$_4$OH. The gel preparation process started when both solutions were mixed together under vigorous stirring. After the peptization process, the volume of the solution decreased and a suspension was produced. Depending on the preparation conditions, the resultant suspension was white-blue or opaque with a high viscosity. The viscous solution was dried at 100 °C in an oven for 24 h. After being washed with ethanol and dried at 100 °C in an oven for 10 h, a yellow-white powder was obtained. Finally, the prepared powder was heat-treated at temperatures ranging from 200 to 600 °C for 3 h.

Several techniques were employed for characterization of the powders. The crystallization process of the precursor was evaluated by thermogravimetry-differential thermal analysis (TG-DTA, SETRAM, France), using a sample weight of about 24 mg and a heating rate of 10 °C/min. The crystalline phases and average crystallite sizes after heat-treatment were identified by powder X-ray diffraction (XRD, CuK$_{α}$, 40 kV, 30 mA, Rigaku, Japan) with a scan rate of 3 °C/min. The particle size and microstructural morphology of the nanocrystalline powders were observed by scanning electron microscopy (SEM, JSM-35CF, JEOL).

**Results and Discussion**

The preparation of the TiO$_2$ colloids in the nanometre range can be effectively conducted through the hydrolysis and condensation of titanium alkoxides in aqueous media. In the presence of water, alkoxides are hydrolysed and subsequently polymerized to form a three-dimensional oxide network. These reactions can be schematically represented as follows:

\[
\text{Ti(OR)}_4 + 4\text{H}_2\text{O} \rightarrow \text{Ti(OH)}_4 + 4\text{ROH} \quad \text{(hydrolysis)} \quad (1)
\]

\[
\text{Ti(OH)}_4 \rightarrow \text{TiO}_2 \cdot x\text{H}_2\text{O} + (2-x)\text{H}_2\text{O} \quad \text{(condensation)} \quad (2)
\]

where R is ethyl, i-propyl, n-butyl, etc. [43]. It is well known that the tetravalent cations are too acidic so that the nucleation of the stable hydroxide Ti(OH)$_4$ cannot occur. Water molecules formed according to reaction (2) always bear a positive partial charge. Therefore, oxolation and olation can proceed simultaneously during nucleation and growth leading to an amorphous oxide TiO$_2$·nH$_2$O where the number n of water molecules depends on the experimental conditions. Depending on the experimental procedure, the precipitation of TiO$_2$ leads to rutile or anatase phases [44, 45]. The stage of deoxilation prior to olation can be controlled by adjusting the pH and initial water concentration. This control leads to precipitation of anatase nanoparticles of TiO$_2$ in the experimental procedure.

Table 1 shows the effect of catalysts of NH$_4$OH/HCl, the molar ratio of catalyst/TTIP, and pH on the morphology and crystalline structure of the TiO$_2$. When the catalyst is NH$_4$OH or there is none in the solution with the pH level from 10.07 to 5.04, powder forms with amorphous

phases were observed. Otherwise, when the catalyst is HCl in the solution with the pH level from 3.96 to 1.9, an agglomerated granular and bulk form with amorphous and anatase phases were observed. Therefore, TiO$_2$ nanoparticles with various morphologies and crystal structures were synthesized by the hydrolysis reaction of titanium tetra-isopropoxide using the molar ratio of catalyst and TTIP with various pH values in acid and base solutions. The morphology and phase transformation of TiO$_2$ powder prepared by hydrolysis of titanium tetra-isopropoxide were strongly influenced by the presence of the catalysts HCl and NH$_4$OH.

Fig. 1 shows SEM micrographs of the TiO$_2$ powders dried at 100 °C with NH$_4$OH as the base catalyst or none. The TiO$_2$ powder exhibited a homogeneous spherical morphology and a particle size distribution with sizes of 100-200 nm for pH 10.67 in Fig. 1(a) and 9.45 in Fig. 1(b). The particle morphology and particle size distribution had an inhomogeneous tendency to decrease depending on a relatively lower pH value of 7.77 in Fig. 1(c) and 5.04 in Fig. 1(d). On the other hand, Fig. 2 shows SEM micrographs of the TiO$_2$ powders dried at 100 °C with HCl as the catalyst or none. It showed a granular form for pH 3.96 in Fig 2(a) and a bulk-like form for pH 2.95(b), 2.12(c), 1.92(d).

The effect of pH on the TiO$_2$ nanopowder after heat-treatment was evaluated for the crystalline phase and size. Fig. 3 shows XRD patterns of TiO$_2$ powders calcined for 3 h at (a) 200, (b) 300, (c) 400 and (d) 500 °C with NH$_4$OH as the catalyst; (A) NH$_4$OH/TTIP = 0.5, (B) NH$_4$OH/TTIP = 0.25. The representative (101) plane diffraction peak at 25.3° is used for anatase and (110) peak at 27.5° for rutile. This shows that the anatase phase was observed above 200 °C, while the rutile phase above 500 °C. In the case of (A) NH$_4$OH/TTIP = 0.5 (pH 9.45), the rutile phase was increased compared to the case of (B) NH$_4$OH/TTIP = 0.25 (pH 7.77) in Fig. 3. The effect of calcination temperature on the crystallization with HCl as the catalyst was also investigated. Fig. 4 shows XRD patterns of TiO$_2$ powders calcined for 3 h at (a) dried, (b) 200, (c) 300 and (d) 400 and (e) 500 °C with HCl as the catalyst; (A) HCl/TTIP = 0.25, (B) HCl/TTIP = 0.5 in Fig. 4. It shows that the anatase phase was observed above 100 °C and the rutile phase was observed above 500 °C in the case of (A) HCl/TTIP =
Reaction morphology and the effect of pH on the preparation of TiO$_2$ nanoparticles by a sol-gel method

0.25 (pH 2.12), while the rutile phase was increased above 400 °C in the case of (B) HCl/TTIP = 0.5 (pH 1.92) in Fig. 4.

Table 2 shows the formation of various phases for the TiO$_2$ powders as a function of pH and the calcination temperature (Am : amorphous, A : anatase, R : rutile). When the temperature was raised, the anatase phase transformed to the rutile phase, which could be attributed to the thermally-promoted crystallite growth. In particular, the phase transformation of amorphous Ti(OH)$_4$ to anatase TiO$_2$ and anatase to rutile were significantly activated by the HCl catalyst. On the other hand, the phase transformation and the crystallization of the particles were not activated by the NH$_4$OH catalyst. This reveals that nucleation and growth of the rutile phase have been initiated at temperatures somewhere from 400-600 °C. It may be assumed that the growth of rutile crystallization was affected by the pH value of acid.

Fig. 4 shows the average calculated weight fractions of anatase as a function of the calcination temperature. The existing phase in the powder after heat-treatment was identified by XRD. The weight fraction of rutile in the powders was estimated in the following equation [46].

Fig. 5 shows the average crystallite size of the heat-treated powders

*X : amorphous, A : anatase, R : rutile

Fig. 5. Calculated rutile weight fractions of the TiO$_2$ powders as a function of pH.

The anatase to rutile transformation is shown as a function of the temperature and pH level in Fig. 5. It is noted that the temperature of the rutile ratio is shifted to a lower temperature of 300-400 °C in strong acid. This is attributed to the high surface energy of the particles in strong acid. Therefore, the rutile ratio increases rapidly depending on the lower pH level as well as at higher temperatures, while increases slowly at the higher pH level. It is assumed that the anatase phase has been eliminated following large rutile particles with poor agglomeration, and aggregation takes place during the particle growth process at higher temperatures.

The average crystallite size of the heat-treated powders

X = 1/(1 + 0.8 I$_A$/I$_R$)  

(3)

where,

X : weight fraction of rutile in the powders
I$_A$ : X-ray integrated intensity of the strongest peaks of anatase (2θ = 25.3°, (101) plane)
I$_R$ : X-ray integrated intensity of the strongest peaks of rutile (2θ = 27.5°, (110) plane)
was calculated using X-ray diffractometry line broadening method through the following Sherrer’s equation [47].

\[ D = \frac{K\lambda}{\beta \cos \theta} \]  

(4)

where D is the crystallite size, \( \lambda \) is wavelength of the radiation (\( \lambda = 1.5418 \) Å), \( \theta \) is Bragg’s angle, \( \beta \) is the full width at half maximum (radian) and K is constant (0.9-1.4). Fig. 6 shows the average grain size of anatase as a function of calcination temperature. The average sizes of anatase TiO\(_2\) nanoparticles were in the range of 10-48 nm at calcination temperatures between 100 and 500 °C. Anatase TiO\(_2\) nanoparticles could be obtained above 300 °C in acid (pH 2.12, pH 1.92) with sizes of 10-27 nm, while in the base (pH 10.67, pH 1.92) with sizes 16-47 nm. The anatase nanoparticles could be prepared at a lower temperature in the base solution, and at above 300 °C in the acid solution with a lower particle size compared to the base solution at the same temperature between 300 and 500 °C. It is considered that the remaining amount of anatase became very small in the acid solution, because the phase transformation from anatase to rutile was significantly activated in the acid solution at an increasing temperature. It is noted that nucleation and growth of the rutile phase have been initiated at temperatures from 400-600 °C. Consequently, the phase transformations of amorphous Ti(OH)\(_4\) to anatase TiO\(_2\) and anatase to rutile was significantly activated by the HCl catalyst and temperature. On the other hand, the phase transformation and the crystallization of the particles were not activated by the NH\(_4\)OH catalyst.

Conclusions

TiO\(_2\) nanoparticles with a homogeneous particle distribution were successfully prepared using a hydrolysis reaction of titanium tetra-isopropoxide. The morphology and phase transformation of TiO\(_2\) particles prepared by hydrolysis of titanium tetra-isopropoxide were strongly influenced by the presence of catalysts. In the case of NH\(_4\)OH, the morphology of the TiO\(_2\) powder exhibited a powder form. In the case of HCl, it showed a bulk or granular form. The phase transformations of amorphous Ti(OH)\(_4\) to anatase TiO\(_2\) and anatase to rutile were significantly activated by the HCl catalyst. On the other hand, the phase transformation and the crystallization of the particles were not activated by the NH\(_4\)OH catalyst.
