Eu and Dy-doped strontium aluminate is a long-lasting phosphor for practical applications in displays and emergency signage. SrAl$_2$O$_4$ synthesized samples have been systematically investigated by PXRD, SEM and photoluminescence. The optimization of the properties has been determined in terms of varying concentrations of Sr$^{2+}$ (alkali metal ion concentration) and the dopant concentrations of Eu$^{2+}$ and Dy$^{3+}$. A new method of synthesis requiring hydrate solutions of the metal ions and cellulose precursor called Liquid Phase Precursor method (LPP) has been adapted. The emission intensity was observed to be higher for the prepared samples compared to a commercial product prepared with a solid state reaction method.

Key words: Emission properties, PXRD, SEM, Dopant concentration, Persistent luminescence.

Introduction

In sensing applications such as bioimaging, persistent luminescent particles have found new applications apart from their usual usage as photostimulated storage phosphors for optical information write-in and read-out processes on imaging plates [1].

Materials persistent luminescence properties with a persistence time of more than 5 h upon stimulated radiation are of fundamental interest in applications such as signage, blackouts, emergency rescue, guidance systems, and luminescent watches [2-6].

Spectrum fingerprint anti-counterfeiting fiber applications are made of rare-earth strontium aluminates, which have stable physical and luminescent performance [7]. Persistent luminescence is observed in strontium aluminate phosphors with an initial rapid decay upon doping with Eu$^{2+}$ ions or upon co-doping with an activator ion. The long afterglow characteristics of the persistent phosphors are explained on the basis of trapping and detrapping mechanisms of Dy$^{3+}$ ion trapping [8]. Persistent luminescence phosphors based on aluminates have interesting properties, such as high radiation intensity, long-lasting photoluminescence, excellent photo resistance, robustness, color purity, and radiation resistance [9]. Moreover, multiphosphor systems such as SrAl$_2$O$_4$: Eu$^{2+}$, Dy$^{3+}$, Sr$_2$Al$_4$O$_9$: Eu$^{2+}$, Dy$^{3+}$, CaAl$_2$O$_4$: Eu$^{2+}$, Nd$^{3+}$, CaSi$_2$O$_6$N$_2$, or Sr$_2$Al$_5$O$_{11}$: Eu$^{2+}$ and Sr$_2$Al$_6$O$_{17}$Cl$_2$ lattices were prepared by spray pyrolysis, microemulsion method, and solid-state synthesis [10-15]. Other advantageous processes reported for the synthesis of SrAl$_2$O$_4$ are sol-gel synthesis, combustion synthesis, and chemical co-precipitation method [16-18].

Persistent phosphorescence or afterglow depends upon the mechanism of photooxidation of Eu$^{2+}$ cations under UV irradiation. When an energetic beam is incident on a phosphor, an electron-hole pair diffuses through the phosphor and transfers its energy to activator ions, which subsequently results in the emission of light. The thermal energy formally releases electrons and holes trapped in defects, and their recombination occurs at radiative emission centers. For rare-earth Eu$^{2+}$-activated phosphors, there are two types of localized centers: C and D types [19]. The type C features Eu$^{2+}$ ions that are photo-ionized by vacuum-ultraviolet excitation and change to Eu$^{3+}$, for which photoconductivity resulting from electrons is observed. The second is type D, in which the excitation of Eu$^{2+}$ by ultraviolet light leads to the liberation of holes to the valence band accompanied by the reduction of Eu$^{2+}$ to Eu$^{3+}$. The holes generate afterglow phosphorescence properties. In a given host, the emission of Eu$^{3+}$ is influenced by the covalency, the size of the cation, the strength of the crystal field, and the alignment.

SrAl$_2$O$_4$ phosphor has been prepared by cellulose-assisted liquid phase precursor method using hydrate solutions of the raw materials impregnated on to the cellulose precursor. This method is apt for reducing the synthesis cost, controlling the shape and size, and creating fair crystallinity and high homogeneity for the synthesis of SrAl$_2$O$_4$ products. Strontium aluminates doped with...
Eu\textsuperscript{2+} and Dy\textsuperscript{3+} with highly emissive properties and long afterglow have been studied.

**Experimental**

We used Sr(NO\textsubscript{3})\textsubscript{2} (50 wt\%, Japan), Al(NO\textsubscript{3})\textsubscript{3} · 9H\textsubscript{2}O (80 wt\%, Samchun Chemical, Korea), DyCl\textsubscript{3} · 3H\textsubscript{2}O (30 wt\%, Japan), and EuCl\textsubscript{3} · 3H\textsubscript{2}O (30 wt\%, Japan) as raw materials for the synthesis of SrAl\textsubscript{2}O\textsubscript{4} phosphors. The raw materials were all dissolved in deionized water to prepare their hydrate solutions and stirred thoroughly to create better homogeneity. The homogeneous hydrate solutions were then impregnated onto cellulose pulp (C\textsubscript{6}H\textsubscript{10}O\textsubscript{5})\textsubscript{n} (lint-free cellulose paper, 49-μm thick, 100% cellulose, Nihon pulp, Japan) at a weight ratio of 1 : 1. The impregnated cellulose pulp was placed in an alumina crucible, rapidly fired at 600 \degree C for 2 h and then at 800 \degree C for 2 h, and finally fired at 1100 \degree C for 2 h in a reducing atmosphere (5H\textsubscript{2}/95N\textsubscript{2}). The cellulose degrades towards 400 \degree C and allows for the early stages of crystallization of the SrAl\textsubscript{2}O\textsubscript{4} phase.

The phase purity of the products was determined by examining the powder X-ray diffraction patterns on a Rigaku X-Ray diffractometer using Cu K\textalpha\ radiation (\(\lambda = 1.5418\) Å) over the 2\theta range of 10-80 \degree. The SEM micrographs of products were obtained using a field emission scanning electron microscope (FE-SEM; XL-30, Philips). The fluorescence spectra were recorded at room temperature using a spectrofluorimeter (PLE/PL Drasa Pro 5300, Korea) with a xenon lamp light source.

**Results and Discussion**

All the samples were prepared by liquid phase precursor method and characterized by powder X-ray diffraction for structural iteration and found to form homogeneous single-phasic strontium aluminates according to JCPDS card no. 10740794. The powder X-ray diffraction pattern of Sr\textsubscript{1.6}Al\textsubscript{2}O\textsubscript{4} : Eu\textsubscript{0.015}Dy\textsubscript{0.03} is shown in figure 1. The structure of the low-temperature monoclinic phase of SrAl\textsubscript{2}O\textsubscript{4} is represented by the 011, 020, 111, 120, 111, 211, 220, 211, 002, 031, and 131 reflections with a P\textsuperscript{2}\textsubscript{1} space group and lattice parameters of a = 8.44 Å, b = 8.81 Å, c = 5.16 Å, and \(\beta = 93.42 \degree\). The monoclinic structure is supported by the corner sharing AlO\textsubscript{4} tetrahedra. The Sr ions are located in two different crystallographic sites that differ only by slight distortion of their square planes and invariably occur in channels of the tetrahedron [20]. The composition change induced no phase transformation. Additional composition data is available in Table 1. Figure 2(i) shows the scanning electron microscopic image of the synthesized SrAl\textsubscript{2}O\textsubscript{4} nanophosphors and a commercial sample. In SEM,

irregular bulky crystallites were observed with agglomeration. The SEM images do not provide insight into the compositional effect on the morphology due to heavy agglomeration. The EDS spectrum shown in Figure 2(ii) reveals agglomerates of the constitutive elements Sr, Al, O, Eu and Dy, characterizing the composition as SrAl$_2$O$_4$:Eu$^{2+}$Dy$^{3+}$. This research was proposed to explain the effect of composition changes on the luminescent properties in SrAl$_2$O$_4$:Eu, Dy phosphors. All the compositions are listed in Table 1. We probed the effect of varying the composition of either the host lattice by varying the Sr concentration or by altering the dopant or the auxiliary ion content, and on the basis of studying the emission or the excitation spectra. As depicted in the SEM images, the powder samples showed heterogeneity, which resulted in the determined luminescence properties.

Concentration dependence of Eu on emission properties of SrAl$_2$O$_4$: Eu, Dy

The emission spectra for commercial and Sr$_{1.7}$Al$_2$O$_4$: Eu$_{0.01}$Dy$_{0.03}$ is shown in Figure 3. A gradual increase in the emission intensity was observed as the Eu concentration was increased from 0.015 to 0.035 moles in Sr$_{1.7}$Al$_2$O$_4$: Eu$_{0.01}$Dy$_{0.03}$ for samples 3 to 5, as shown in Table 1. The characteristic green emission at 525 nm corresponds to the 4f$^6$5d$^1$ → 4f$^7$ transition of Eu$^{2+}$. The ionic radii of Eu$^{2+}$ is 0.117 nm in O$_{h}$, and that of Sr$^{2+}$ is 0.116 nm in O$_{h}$, which is easily replaced by the Sr$^{2+}$ ion in the host lattice, and the emission originates from the excited 4f$^6$ 5d$^1$ configuration of Eu$^{2+}$. The firing in reducing atmosphere is expected to form mainly Eu$^{2+}$ [21]. The Eu$^{2+}$ ions are present in two crystallographically different Sr$^{2+}$ sites with similar environments. The emission maximum observed in the samples prepared by LPP is higher than that observed for the commercial sample. In this study, the concentration was chosen to be optimum for the activator and auxiliary ions while bearing in mind the commercial sample for the emission as well as persistent luminescence. We did not observe any transition at 450 nm, as the band is observed to disappear at higher Eu$^{2+}$ concentration [22]. Our samples prepared by the liquid phase precursor method are shown to have better emissive properties than the commercial product prepared by solid-state method. The sample hydrate solutions impregnated on cellulose after firing yield enhanced emissive properties. The excitation profiles of these are shown in Figure 4, where we observed a broad band at 350 nm for the commercial sample with a small shoulder. Similar spectral features were observed for the prepared samples, but with a red shift ascribed to the synthesis methodology.

Concentration dependence of Dy$^{3+}$

We observed an increase in the emission intensity due to the increase in Dy$^{3+}$ ion concentration while keeping other concentrations constant, as shown in Figure 5. A subtle increase in Dy$^{3+}$ ion concentration with a mole % of 0.010 for composition 8, results in a significant increase in the emission intensity of the sample. To exhibit afterglow, it is essential for a long-lasting phosphor to have trapping levels located at suitable depth on order with the thermal release rate at

Fig. 3. The room-temperature emission spectra at $\lambda_{ex}$ = 365 nm of samples; (a) = 3, (b) = 4, (c) = 5 with varying Eu concentration in Sr$_{1.7}$Al$_2$O$_4$: Eu$_{Dy_{0.03}}$ and commercial sample Sr$_{0.97}$Al$_2$O$_4$: Eu$_{0.01}$Dy$_{0.02}$.

Fig. 4. The room-temperature excitation spectra at $\lambda_{em}$ = 525 nm of samples: (a) = 3, (b) = 4, (c) = 5 with varying Eu concentration in Sr$_{1.7}$Al$_2$O$_4$: Eu$_{Dy_{0.03}}$ and commercial sample Sr$_{0.97}$Al$_2$O$_4$: Eu$_{0.01}$Dy$_{0.02}$.
room temperature. The lifetime of a trapped charge carrier is given as $E_T/k_BT$, which is the ratio of trap depth to the thermal energy. To explain the charge neutrality, we propose that SrAl$_2$O$_4$, which has Sr and oxygen vacancies, enhances the cation deficiency when it is codoped with Dy$^{3+}$ [23]. Dy serves to increase the number and depth of electron traps. The ionization potential of the cation affects the ability of the cation to stabilize the V$_o$. The lower the ionization potential of the cation (Eu$^{2+}$ 25.0eV, Dy$^{2+}$ 41.5eV, Sr$^{2+}$ 43.7eV), the more strongly it is attracted to the V$_o$. Dy$^{3+}$ extends the phosphorescence by completing the change of V$_o$ to electron traps by the Eu$^{2+}$ cation attraction [23]. The excitation spectra observed for the varying Dy concentration showed dissimilar results compared to the results of samples with varied Eu content and those of the commercial sample. Instead of a peak maximum of excitation at 350 nm, it was observed at 420 nm, and only a small shoulder was present at 350 nm.

**Concentration dependence of Sr$^{2+}$**

The emission intensity does not vary monotonically with the activator Eu$^{2+}$ ion, but depends upon the change in Sr$^{2+}$ ion concentration. Yuan et al. studied the effect of Sr concentration in Sr$_2$Al$_2$O$_{25}$ : Eu$^{2+}$, Dy$^{3+}$ phosphors on the luminescence properties and observed that Sr-rich phosphors have poorer afterglow properties than Al-rich phosphors [24]. But for the liquid-phase-prepared SrAl$_2$O$_4$ phosphors, we observed that the effect is different from those of the samples prepared by solid-state method. We observed enhanced emission intensity for the Sr-rich phosphors in SrAl$_2$O$_4$ phosphors, as shown in figure 5.

**Conclusions**

By varying the compositions, the effect of variation has been studied in SrAl$_2$O$_4$ phosphors codoped with Eu and Dy using a liquid phase precursor synthesis method. The luminescence properties show a peak maximum that is higher in the prepared samples compared to the commercial product prepared with a solid-state reaction method. The characteristic green emission observed has been interpreted by studying the substitution of varying activator ions. The emission intensity was found to be significantly increased. Our analysis indicates that the effect of varying Dy content resulted in different excitation behaviors from those observed for the Eu ion composition effect. However, the emission spectra were observed to be similar in the two ascribed measurements.
